Random walks on finite lattices with multiple traps: Application to particle-cluster aggregation

Abstract

For random walks on finite lattices with multiple (completely adsorbing) traps, one is interested in the mean walk length until trapping and in the probability of capture for the various traps (either for a walk with a specific starting site, or for an average over all nontrap sites). We develop the formulation of Montroll to enable determination of the large-lattice-size asymptotic behavior of these quantities. (Only the case of a single trap has been analyzed in detail previously.) Explicit results are given for the case of symmetric nearest-neighbor random walks on two-dimensional (2D) square and triangular lattices. Procedures for exact calculation of walk lengths on a finite lattice with a single trap are extended to the multiple-trap case to determine all the above quantities. We examine convergence to asymptotic behavior as the lattice size increases. Connection with Witten-Sander irreversible particle-cluster aggregation is made by noting that this process corresponds to designating all sites adjacent to the cluster as traps. Thus capture probabilities for different traps determine the proportions of the various shaped clusters formed. (Reciprocals of) associated average walk lengths relate to rates for various irreversible aggregation processes involving a gas of walkers and clusters. Results are also presented for some of these quantities.

(Received 20 May 1985)

For random walks on finite lattices with multiple (completely adsorbing) traps, one is interested in the mean walk length until trapping and in the probability of capture for the various traps (either for a walk with a specific starting site, or for an average over all nontrap sites). We develop the formulation of Montroll to enable determination of the large-lattice-size asymptotic behavior of these quantities. (Only the case of a single trap has been analyzed in detail previously.) Explicit results are given for the case of symmetric nearest-neighbor random walks on two-dimensional (2D) square and triangular lattices. Procedures for exact calculation of walk lengths on a finite lattice with a single trap are extended to the multiple-trap case to determine all the above quantities. We examine convergence to asymptotic behavior as the lattice size increases. Connection with Witten-Sander irreversible particle-cluster aggregation is made by noting that this process corresponds to designating all sites adjacent to the cluster as traps. Thus capture probabilities for different traps determine the proportions of the various shaped clusters formed. (Reciprocals of) associated average walk lengths relate to rates for various irreversible aggregation processes involving a gas of walkers and clusters. Results are also presented for some of these quantities.

I. INTRODUCTION

Extensive results are available characterizing random walks on a finite lattice of N sites (with periodic boundary conditions) having a *single* (completely adsorbing) trap l_T .¹⁻⁵ The basic quantities of interest are the mean numbers of steps until trapping, $\langle n \rangle_l$, for walks starting from various lattice sites $l \neq l_T$ (the trap position). These, of course, have a natural interpretation as first passage times on a corresponding perfect lattice. The characteristics of the lattice-averaged walk length,

$$\langle n \rangle = (N-1)^{-1} \sum_{l \neq l_T} \langle n \rangle_l,$$

are of particular interest.

For sites l_T^* , adjacent to l_T , one has that $\langle n \rangle_{l_T^*} = N-1$ for walks with jumps to neighboring sites only, independent of lattice structure.² For general $l = (l_1, l_2, \dots)$ on a hypercubic lattice, where all sites except $l_T = (0, 0, \dots)$ have identical jump rates $p(m)$ [for a jump of (m_1, m_2, \dots) lattice vectors], we define $\sigma_k^2 = \sum_k m_k^2 p(m)$ and $\|l\| = (\sum_k l_k^2 / \sigma_k^2)^{1/2}$. Then one has that²

$$\langle n \rangle_l \sim \begin{cases} \left[\frac{\ln \|l\|}{\pi \sigma_1 \sigma_2} + O(1) \right] N & \text{in 2D} \\ [u + O(\|l\|^{2-d})] N & \text{in } d \geq 3D, \end{cases} \quad (1.1a)$$

$$(1.1b)$$

for large $\|l\|$ ($\ll N$), where $u^{-1} (=0.340537\dots)$ for a simple-cubic lattice) is the probability of escape (i.e., nonreturn) for a walker starting at the origin on an infinite, perfect lattice. From (1.1), it is also clear that³

$$\langle n \rangle \sim \begin{cases} \frac{N \ln N}{2\pi \sigma_1 \sigma_2} & \text{in 2D} \\ uN & \text{in } d \geq 3D, \end{cases} \quad (1.2)$$

where we have used that $\ln \|l\| \sim \ln N^{1/2}$ for most contributions in 2D. If S_n denotes the mean number of *distinct* sites visited by an n -step walk on an infinite perfect lattice, then one can show that (1.2) implies^{6(a)} $S_{\langle n \rangle} \sim N$. This result, if also true for the corresponding finite lattice S_n , has the interpretation that the walker, on average, visits all distinct nontrapping sites once before being trapped.^{6(b)} Another perspective on the behavior of $\langle n \rangle$ follows from assuming that the (average) probability for trapping on the n th step is $(1-1/N)^{S_n-1}(1/N)$, so that

$$\langle n \rangle \sim \sum_{n=1}^{\infty} n(1-1/N)^{S_n-1}(1/N)$$

[which has been shown to agree with (1.2) in $d \geq 3D$].⁷

Efficient algorithms, exploiting lattice symmetry, have been developed to calculate $\langle n \rangle_l$ (and thus $\langle n \rangle$) directly and exactly for finite lattices (results for $N \sim 10^3$ are readily obtained).⁸⁻¹⁰ Such results for $\langle n \rangle$ have been compared with those obtained from the first few terms of large- N asymptotic expansions whose first terms are given by (1.2). There is close agreement even for small lattice sizes. These techniques can be readily adapted to model modifications such as biased walks and alternative boundary conditions.

Montroll has extended the above formulation to characterize a random walk in the presence of multiple (completely adsorbing) traps, denoted here by $L = \{l_T^1, l_T^2, \dots, l_T^t\}$ for t traps.¹¹ Again the site-specific walk lengths until trapping, $\langle n \rangle_l$, for $l \notin L$, and the average walk length, $\langle n \rangle = (N-t)^{-1} \sum_{l \notin L} \langle n \rangle_l$, are of par-

ticular interest. As the appropriate expressions for these quantities are rather complicated, little specific analysis has been given. The above discussion suggests that here, *provided* all trap separations are $O(1)$, (1.2) should still hold in 2D. Consequently the influence of multiple traps (as compared with a single trap) will only be seen in the coefficient of the $O(N)$ correction term. However, for $d \geq 3D$, $\lim_{N \rightarrow \infty} \langle n \rangle / N$ should be lowered from u by the presence of multiple traps. This behavior will be confirmed below. The above single-trap procedures for direct calculation of $\langle n \rangle_l$ can be extended to the multiple-trap case, but ease of calculation is greatly enhanced by the presence of trap-lattice symmetries. The concept of lattice *decimation*,⁹ wherein successively larger regions of the lattice are replaced by traps, also provides some systematic simplifying features. For the multiple-trap case, trapping or capture probabilities for individual traps are nontrivial for walks starting from a specific site. (The trap-specific mean walk lengths are also nontrivial.) One can have traps of distinct symmetry for $t \geq 3$, and, in this case, lattice-averaged trapping probabilities become nontrivial and lattice-averaged trap-specific walk lengths vary from $\langle n \rangle$. Finally, we note that there has been some analysis of the case of a periodic array of traps (on a periodic lattice).¹²

The multiple-trap problem has obvious application to the description of particle-cluster aggregation where a single randomly walking particle, upon reaching a site adjacent to the immobile cluster, sticks (or coalesces) irreversibly (cf. the Witten-Sander model for the diffusion-limited aggregation of fractal-like clusters¹³). Here sites adjacent to the cluster are assigned as (completely adsorbing) traps, i.e., one decimates sites adjacent to the appropriate cluster-shaped set of (trap) sites (see Fig. 1). We note that the cluster shape distribution in the Witten-Sander model is determined by the characteristics of an appropriate set of $N \rightarrow \infty$ trapping probabilities.¹³ Calculation of site-specific walk lengths allows determination of the average over all sites external to the decimated cluster. (Reciprocals of) such average walk lengths relate to rates of destruction of immobile clusters, with a specific shape, by irreversible aggregation with walkers in a gas of random walkers and immobile clusters. Determination of shape-specific cluster creation rates requires a more detailed knowledge of trap-specific capture probabilities.

Before outlining this contribution, we describe briefly work on other aspects of, and models for, multiple-trap problems. One can consider the effect of traps on the

probability of return to the origin (for finite or infinite lattice).¹⁴ Problems involving a random distribution of traps naturally arise in modeling exciton transport in photosynthetic processes. Processes where "regular" sites have a nonzero trapping probability were also considered here. There is a large body of work directed at analyzing transport and/or diffusion characteristics of walks on imperfect lattices.¹⁴

In Sec. II, we first review Montroll's generating-function formulation for walks on a finite lattice with multiple traps.¹¹ Expressions for trapping probabilities are introduced, and these together with Montroll's expressions for walk lengths are expressed in a simplified, more convenient form. Explicit expressions are given in cases of just a few traps. For lattice-averaged walk lengths, we give some indication of behavior for large connected compact clusters of traps. Explicit large- N asymptotic results are given in Sec. III for symmetric, nearest-neighbor random walks on a square lattice. There is also some discussion of the corresponding triangular-lattice problem. In Sec. IV, we show how matrix techniques for exact calculation of walk lengths, on finite lattices with a single trap, extend simply to the multiple-trap case and can also be used to calculate trapping probabilities. The relationship of the matrix structure and (reduced) walk lengths for a decimated problem to those of the original problem is elucidated. Extensive numerical results are given for the case of a square lattice. Finally, some concluding remarks are made in Sec. V, and application of these results to particle-cluster aggregation models is indicated.

II. GENERATING-FUNCTION FORMULATION AND ANALYSIS OF THE MULTIPLE-TRAP PROBLEM

The development presented here is based on that of Montroll.¹¹ The set of t traps is denoted by $L = \{l_T^1, l_T^2, \dots, l_T^t\}$. The most basic quantity for this process is the probability $P_n(l)$ that the walker is at site l after n steps, given that it started at l^0 , so $P_0(l) = \delta_{l,l^0}$. The corresponding generating function is given by $P(l) \equiv \sum_{n=0}^{\infty} z^n P_n(l)$. Since clearly $\sum_l P_n(l) = 1$, for all n , one has that $\sum_l P(l) = (1-z)^{-1}$.

The probability of trapping (or capture) at $l_T^i \equiv l^i$ is trivially $P_{\infty}(l^i) \equiv \lim_{n \rightarrow \infty} P_n(l^i)$. Since one has

$$\begin{aligned} (1-z)P(l^i) &\equiv \sum_{n=1}^{\infty} z^n [P_n(l^i) - P_{n-1}(l^i)] \\ &\equiv P_{\infty}(l^i) + (1-z) \sum_{n=1}^{\infty} z^n [P_n(l^i) - P_{\infty}(l^i)], \end{aligned} \quad (2.1)$$

it follows that

$$P_{\infty}(l^i) = \lim_{z \rightarrow 1} (1-z)P(l^i). \quad (2.2)$$

Since the probability of trapping at l^i on the n th step is $P_n(l^i) - P_{n-1}(l^i)$, we conclude that the mean walk length $\langle n \rangle_{l^0 \rightarrow l^i}$ from l^0 to l^i is given by

FIG. 1. Aggregation with a bent trimer; adjacent sites which have been decimated to traps are denoted by T .

$$\begin{aligned} \langle n \rangle_{l^0 \rightarrow l^i} &= \frac{\sum_{n=1}^{\infty} n [P_n(l^i) - P_{n-1}(l^i)]}{\sum_{n=1}^{\infty} [P_n(l^i) - P_{n-1}(l^i)]} \\ &= \frac{\frac{\partial}{\partial z} [(1-z)P(l^i)]_{z=1}}{P_{\infty}(l^i)}. \end{aligned} \quad (2.3)$$

It is now clear that the mean walk length from l^0 for capture at any trap is¹¹

$$\langle n \rangle_{l^0} = \frac{\partial}{\partial z} \{ (1-z)[P(l^1) + P(l^2) + \cdots + P(l^t)] \}_{z=1}. \quad (2.4)$$

Montroll has provided expressions for $P(l)$ in terms of the generating function, $G(l)$, for random walks (starting at the origin) on a corresponding perfect lattice, as¹¹

$$P(l) = G(l - l^0) + \sum_{k=1}^t [(1-z)G(l - l^k) + \delta_{l, l^k}] P(l^k). \quad (2.5)$$

A simultaneous set of equations is provided by (2.5) for the $P(l^k)$. Solving these by Cramer's rule yields¹¹

$$P(l^k) = (1-z)^{-1} \begin{vmatrix} G_{11} & \cdots & G_{1k-1} & G_{10} & G_{1k+1} & \cdots & G_{1t} \\ G_{21} & & G_{2k-1} & G_{20} & G_{2k+1} & & G_{2t} \\ G_{31} & & G_{3k-1} & G_{30} & G_{3k+1} & & G_{3t} \\ \vdots & & \vdots & \vdots & \vdots & & \vdots \end{vmatrix} / \det\{G_{ij}\}, \quad (2.6)$$

where $G_{ij} = G(l^i - l^j) = G_{ji}$, and i, j in $\det\{G_{ij}\}$ run from 1 through t . Equation (2.6) allows calculation of various quantities for a walker starting at a specific site l^0 . Corresponding averages over $l^0 \notin L$ can be obtained in terms of

$$\bar{P}(l^k) = \frac{1}{N-t} \sum_{l^0 \notin L} P(l^k). \quad (2.7)$$

Since

$$\sum_{l^0 \notin L} G_{j0} = \sum_{l^0} G_{j0} - \sum_{k=1}^t G_{jk},$$

and

$$\sum_{l^0} G_{j0} = \sum_n z^n \sum_{l^0} G_n(l^j - l^0) = (1-z)^{-1},$$

we conclude that

$$(1-z)\bar{P}(l^k) = \frac{-1}{N-t} + \frac{1}{(N-t)(1-z)} \begin{vmatrix} G_{11} & \cdots & G_{1k-1} & 1 & G_{1k+1} & \cdots & G_{1t} \\ G_{21} & & G_{2k-1} & 1 & G_{2k+1} & & G_{2t} \\ \vdots & & \vdots & \vdots & \vdots & & \vdots \end{vmatrix} / \det\{G_{ij}\}. \quad (2.8)$$

To reduce these expressions further, it is necessary to analyze in more detail the generating function, $G(l)$, for random walks on a perfect lattice. For a finite periodic d -dimensional lattice where $N = L^d$, one has that

$$G(l) = \frac{1}{L^d} \left[\prod_{j=1}^d \sum_{k_j=0}^{L-1} \exp(2\pi i l \cdot k / L) / [1 - z \lambda(2\pi k / L)] \right], \quad (2.9)$$

where $\lambda(\theta) = \sum_l P(l) \exp(il \cdot \theta)$, so

$$G(l) = \frac{1}{N(1-z)} + \Phi(l, z), \quad (2.10)$$

and $\Phi(l, 1)$ is finite. Previous detailed analysis has shown that²

$$\Phi(0, z) \sim (c_1 \ln N + c_2 + c_3 N^{-1} + \cdots) + O(1-z)^{1/2} \quad \text{in 2D}, \quad (2.11a)$$

where $c_1 = (2\pi\sigma_1\sigma_2)^{-1}$ for a square lattice, and the first few c_i have been calculated for various 2D lattices. One can also deduce from previous work that

$$\Phi(0, z) \sim (u + c_2 N^{-1/d} + \cdots) + O(1-z)^{1/2} \quad \text{in } d \geq 3D. \quad (2.11b)$$

Given these results, we naturally make the decomposition $\Phi(l, z) = \Phi(0, z) + \epsilon(l, z)$, and express quantities of interest in terms of $\Phi(0, z)$ and $\epsilon_{ij} = \epsilon(l^i - l^j, z)$ as $z \rightarrow 1$.

The first step is to exhibit explicitly, through $G(0)$ factors, any $z \rightarrow 1$ singular behavior in the determinants appearing in (2.6) and (2.8). We thus note that

$$\begin{vmatrix} G_{11} & \cdots & G_{1k-1} & 1 & G_{1k+1} & \cdots \\ G_{21} & & G_{2k-1} & 1 & G_{2k+1} & \\ \vdots & & \vdots & \vdots & \vdots & \end{vmatrix} = \begin{vmatrix} \epsilon_{11} & \cdots & \epsilon_{1k-1} & 1 & \epsilon_{1k+1} & \cdots \\ \epsilon_{21} & & \epsilon_{2k-1} & 1 & \epsilon_{2k+1} & \\ \vdots & & \vdots & \vdots & \vdots & \end{vmatrix} \quad (\text{nonsingular}), \quad (2.12a)$$

$$\begin{vmatrix} G_{11} & \cdots & G_{1k-1} & G_{10} & G_{1k+1} & \cdots \\ G_{21} & & G_{2k-1} & G_{20} & G_{2k+1} & \\ \vdots & & \vdots & \vdots & \vdots & \end{vmatrix} = G(0) \begin{vmatrix} \epsilon_{11}-\epsilon_{10} & \cdots & \epsilon_{1k-1}-\epsilon_{10} & 1 & \epsilon_{1k+1}-\epsilon_{10} & \cdots \\ \epsilon_{21}-\epsilon_{20} & & \epsilon_{2k-1}-\epsilon_{20} & 1 & \epsilon_{2k+1}-\epsilon_{20} & \\ \vdots & & \vdots & \vdots & \vdots & \end{vmatrix} \\ + \begin{vmatrix} \epsilon_{11} & \cdots & \epsilon_{1k-1} & \epsilon_{10} & \epsilon_{1k+1} & \cdots \\ \epsilon_{21} & & \epsilon_{2k-1} & \epsilon_{20} & \epsilon_{2k+1} & \\ \vdots & & \vdots & \vdots & \vdots & \end{vmatrix}, \quad (2.12b)$$

and

$$\det\{G_{ij}\} = G(0) \left(\begin{vmatrix} 1 & \epsilon_{12} & \cdots & \epsilon_{1t} \\ 1 & \epsilon_{22} & & \epsilon_{2t} \\ \vdots & \vdots & & \vdots \end{vmatrix} + \begin{vmatrix} \epsilon_{11} & 1 & \epsilon_{13} & \cdots & \epsilon_{1t} \\ \epsilon_{21} & 1 & \epsilon_{23} & & \epsilon_{2t} \\ \vdots & \vdots & \vdots & & \vdots \end{vmatrix} + \cdots + \begin{vmatrix} \epsilon_{11} & \cdots & \epsilon_{1t-1} & 1 \\ \epsilon_{21} & & \epsilon_{2t-1} & 1 \\ \vdots & & \vdots & \vdots \end{vmatrix} \right) + \det\{\epsilon_{ij}\}. \quad (2.13)$$

Note that the symmetric sum over the determinants (2.12a), or over those constituting the coefficient of $G(0)$ in (2.12b) [i.e., the coefficient of $G(0)$ in (2.13)], equals

$$\begin{vmatrix} 1 & \epsilon_{12}-\epsilon_{11} & \cdots & \epsilon_{1t}-\epsilon_{11} \\ 1 & \epsilon_{22}-\epsilon_{21} & & \epsilon_{2t}-\epsilon_{21} \\ \vdots & \vdots & & \vdots \end{vmatrix} = \begin{vmatrix} \epsilon_{11}-\epsilon_{12} & 1 & \epsilon_{13}-\epsilon_{12} & \cdots & \epsilon_{1t}-\epsilon_{12} \\ \epsilon_{12}-\epsilon_{22} & 1 & \epsilon_{23}-\epsilon_{22} & & \epsilon_{2t}-\epsilon_{22} \\ \vdots & \vdots & \vdots & & \vdots \end{vmatrix} = \cdots (\equiv S_t, \text{ say}). \quad (2.14)$$

It now follows that

$$P_{\infty}(l^k) = \begin{vmatrix} \epsilon_{11}-\epsilon_{10} & \cdots & \epsilon_{1k-1}-\epsilon_{10} & 1 & \epsilon_{1k+1}-\epsilon_{10} & \cdots \\ \epsilon_{21}-\epsilon_{20} & & \epsilon_{2k-1}-\epsilon_{20} & 1 & \epsilon_{2k+1}-\epsilon_{20} & \\ \vdots & & \vdots & \vdots & \vdots & \end{vmatrix} / S_t, \quad (2.15)$$

$$\bar{P}_{\infty}(l^k) = \frac{N}{N-t} \begin{vmatrix} \epsilon_{11} & \cdots & \epsilon_{1k-1} & 1 & \epsilon_{1k+1} & \cdots \\ \epsilon_{21} & & \epsilon_{2k-1} & 1 & \epsilon_{2k+1} & \\ \vdots & & \vdots & \vdots & \vdots & \end{vmatrix} / S_t - \frac{1}{N-t}, \quad (2.16)$$

where the ϵ_{ij} are now evaluated at $z=1$. Thus one has for a single trap ($t=1$) trivially $P_{\infty}(l^1) = \bar{P}_{\infty}(l^1) = 1$, for a pair of traps ($t=2$)

$$P_{\infty}(l^1) = \frac{\epsilon_{12} + \epsilon_{20} - \epsilon_{10}}{2\epsilon_{12}}, \quad (2.17) \\ P_{\infty}(l^2) = \frac{\epsilon_{12} + \epsilon_{10} - \epsilon_{20}}{2\epsilon_{12}},$$

so $\bar{P}_{\infty}(l^1) = \bar{P}_{\infty}(l^2) = \frac{1}{2}$ (as must be the case since both traps are equivalent), and for a triple of traps ($t=3$)

$$S_3 \cdot P_{\infty}(l^1) = \epsilon_{23}(\epsilon_{12} + \epsilon_{13} - \epsilon_{23}) + \epsilon_{23}(\epsilon_{20} + \epsilon_{30} - 2\epsilon_{10}) \\ + (\epsilon_{12} - \epsilon_{13})(\epsilon_{30} - \epsilon_{20}), \quad (2.18)$$

$$S_3 \cdot \bar{P}_{\infty}(l^1) = \epsilon_{23}(\epsilon_{12} + \epsilon_{13} - \epsilon_{23}) \\ + \frac{1}{N-3} [\epsilon_{23}(\epsilon_{12} + \epsilon_{13} - 2\epsilon_{23}) + (\epsilon_{12} - \epsilon_{13})^2], \quad (2.19)$$

where

$$S_3 = 2(\epsilon_{12}\epsilon_{23} + \epsilon_{13}\epsilon_{23} + \epsilon_{12}\epsilon_{13}) - \epsilon_{12}^2 - \epsilon_{13}^2 - \epsilon_{23}^2,$$

and corresponding expressions for traps l^2 and l^3 are obtained by permutation of indices. For the special case of a connected triple of traps where l^1 and l^2 , l^2 and l^3 are adjacent, so $\epsilon_{12} = \epsilon_{23} = \epsilon_{NN} (= -1, \text{ as shown below})$, and $\epsilon_{13} = -1 - \rho$, one has that

$$\bar{P}_{\infty}(l^{1,3}) : \bar{P}_{\infty}(l^2) \\ = [1 + \rho/(N-3)] : [(1-\rho) - 2\rho/(N-3)]. \quad (2.20)$$

Note that it is possible for l^2 and l^3 to also be adjacent

($\rho=0$) on a triangular lattice wherein (2.20) shows that the $\bar{P}_\infty(l^i)$ are equal (as required).

For a multiple-trap problem where all sites within hopping range of a particular trap l_T^{isol} are *also* traps, it is clear that the walker can never reach l_T^{isol} , and thus $P_\infty(l_T^{\text{isol}}) = \bar{P}_\infty(l_T^{\text{isol}}) = 0$. Such a condition obviously implies complicated relationships between the ϵ_{ij} for associ-

ated geometrical configurations. In the next section we consider one such simple example.

Let us now consider the mean walk length, $\langle n \rangle_{l^0}$, from a specific starting site l^0 , and the average walk length $\langle n \rangle = (N-t)^{-1} \sum_{l^0 \notin L} \langle n \rangle_{l^0}$. From (2.4), (2.6), and (2.12)–(2.14), one has that

$$\begin{aligned} \langle n \rangle_{l^0} &= \frac{\partial}{\partial z} \left[\frac{G(0) \cdot S_t + \sum_{k=1}^t \begin{vmatrix} \epsilon_{11} & \cdots & \epsilon_{1k-1} & \epsilon_{10} & \epsilon_{1k+1} & \cdots \\ \epsilon_{21} & & \epsilon_{2k-1} & \epsilon_{20} & \epsilon_{2k+1} & \\ \vdots & & \vdots & \vdots & \vdots & \end{vmatrix}}{G(0) \cdot S_t + \det\{\epsilon_{ij}\}} \right]_{z=1} \\ &= -N \left[\sum_{k=1}^t \begin{vmatrix} \epsilon_{11} & \cdots & \epsilon_{1k-1} & \epsilon_{10} & \epsilon_{1k+1} & \cdots \\ \epsilon_{21} & & \epsilon_{2k-1} & \epsilon_{20} & \epsilon_{2k+1} & \\ \vdots & & \vdots & \vdots & \vdots & \end{vmatrix} - \det\{\epsilon_{ij}\} \right] / S_t, \end{aligned} \quad (2.21)$$

where the ϵ_{ij} are evaluated at $z=1$. Thus for a single trap ($t=1$), one has that $\langle n \rangle_{l^0} = -\epsilon_{10}N$, and for a pair of traps ($t=2$), $\langle n \rangle_{l^0} = \frac{1}{2}(\epsilon_{12} - \epsilon_{10} - \epsilon_{20})N$. The result for $t=1$ is particularly elucidating in providing a direct physical interpretation for the ϵ_{ij} at $z=1$. This result also follows trivially from previous first-passage-time analyses² which further lead us to conclude that, for nearest-neighbor sites, $\epsilon_{ij} \equiv \epsilon_{NN} = -1$, and that

$$\epsilon_{ij} \sim -\ln||i-j||/\pi\sigma_1\sigma_2$$

for an infinite 2D square lattice, $\sim -u$ in $d \geq 3D$, for $||i-j||$ large [cf. (1.1)].

From (2.4), (2.8), (2.13) and (2.14), one has that

FIG. 2. A linear string (square array) of m roughly equally spaced traps of total linear span t ($t^{1/2}$).

$$\begin{aligned} \langle n \rangle &= \frac{1}{N-t} \frac{\partial}{\partial z} \left[\frac{(1-z)^{-1} S_t}{G(0) \cdot S_t + \det\{\epsilon_{ij}\}} \right]_{z=1} \\ &= \frac{N}{N-t} [N\Phi(0,1) + N \det\{\epsilon_{ij}\} / S_t], \end{aligned} \quad (2.22)$$

where the ϵ_{ij} are evaluated at $z=1$. For a single trap ($t=1$), (2.22) reduces to $\langle n \rangle = (N/N-1)[N\Phi(0,1)]$, i.e., only the first term contributes (cf. Refs. 3 and 9), so the second provides the correction associated with the introduction of additional traps (and thus will be *negative*). For a pair of traps ($t=2$), (2.22) becomes

$$\langle n \rangle = \frac{N}{N-2} [\Phi(0,1) + \frac{1}{2}\epsilon_{12}]N,$$

and for a triple ($t=3$),

$$\langle n \rangle = \frac{N}{N-3} [\Phi(0,1) + 2\epsilon_{12}\epsilon_{13}\epsilon_{23}/S_3]N,$$

in which $2\epsilon_{12}\epsilon_{13}\epsilon_{23}/S_3$ reduces to $-\frac{1}{2}(1+\tilde{\epsilon}/4)^{-1}$ for a connected triple where $\epsilon_{ij} = \tilde{\epsilon}$ for the (possibly) nonadjacent pair of traps. We can also deduce from (2.22) that in 2D, $\langle n \rangle \sim c_1 N \ln N$, as in the single-trap case, and that corrections affect the $O(N)$ term, and that in $d \geq 3D$, $\langle n \rangle \sim (u + \det\{\epsilon_{ij}\}/S_t)N$, so corrections affect the dominant large- N behavior.

It is appropriate to note, at this point, that characterization and enumeration of the ϵ_{ij} -product terms in such determinant quantities as $\det\{\epsilon_{ij}\}$ and S_t is quite easily achieved using ideas from flow graph theory, and specifically the Coates graph¹⁵ (see Appendix A).

We are particularly interested in characterizing the behavior of the correction term to the average walk length, $\det\{\epsilon_{ij}\}/S_t$, for a large number of traps (particularly when these form a connected cluster). To illustrate this behavior in 2D, consider the case of a symmetric nearest-neighbor random walk on a square lattice, where

$\sigma_1 = \sigma_2 = 2^{-1/2}$. First consider a linear string of m (roughly) equally spaced traps of total span t (see Fig. 2). We let t become large while holding $m \geq 2$ fixed, so the separation between adjacent traps is $\sim t/m$. Thus one has $\epsilon_{ij} \sim -(2/\pi)\ln(|i-j|t/m)$, assuming that the traps are labeled from left to right $1, 2, 3, \dots$, and so to leading order, for large t , and m fixed, the $\epsilon_{ij} \sim -(2/\pi)\ln t$ are equal. It is then a simple matter to show that¹⁶

$$\det\{\epsilon_{ij}\} \sim (-1)^{m+1}(m-1) \left[-\frac{2}{\pi} \ln t \right]^m$$

and

$$S_t \sim (-1)^{m-1} m \left[-\frac{2}{\pi} \ln t \right]^{m-1},$$

so

$$\langle n \rangle \sim N\Phi(0,1) - N \frac{m-1}{m} \frac{2}{\pi} \ln t,$$

for large t . For any m , this result clearly provides an upper bound on the large- t behavior of the average walk length for a string of t contiguous traps. In fact calculations following indicate that, for a linear string of t contiguous traps (t -lin), one has

$$\langle n \rangle_{t\text{-lin}} \sim N\Phi(0,1) - \frac{2}{\pi} N \ln t. \quad (2.23)$$

For comparison, one naturally considers $\langle n \rangle$ for a square array of m traps of total horizontal and vertical span $t^{1/2}$ (see Fig. 2). Similar arguments to those above show that $\epsilon_{ij} \sim -(2/\pi)\ln t^{1/2} = -(1/\pi)\ln t$, and

$$\langle n \rangle \sim N\Phi(0,1) - N \frac{m-1}{m} \frac{1}{\pi} \ln t,$$

for t large and m fixed. This leads to the speculation that for a contiguous square array of t traps (t -sq), $\langle n \rangle_{t\text{-sq}} \sim N\Phi(0,1) - (1/\pi)N \ln t$, and, more generally, that for a general contiguous compact array of t traps

$$\langle n \rangle \sim N\Phi(0,1) - \frac{2}{\pi} N \ln \mathcal{P}, \quad (2.24)$$

for large t , where \mathcal{P} is a suitably defined perimeter function. Validity of these relationships is investigated in the next section.

The expressions for trap-specific walk lengths are, in general, more complex. Of course for a single trap ($t=1$), these are given by (2.21) and (2.22) with $t=1$. For a pair of traps ($t=2$), one has

$$\begin{aligned} P_\infty(l^1) \langle n \rangle_{l^0 \rightarrow l^1} &= \frac{\partial}{\partial z} \left[\frac{G(0)(-\epsilon_{12} - \epsilon_{20} + \epsilon_{10}) - \epsilon_{12}\epsilon_{20}}{G(0)(-2\epsilon_{12}) - \epsilon_{12}^2} \right]_{z=1} \\ &= \frac{\partial}{\partial z} \left[\frac{\epsilon_{12} + \epsilon_{20} - \epsilon_{10}}{2\epsilon_{12}} \right]_{z=1} + \frac{1}{2} \langle n \rangle_{l^0}, \end{aligned} \quad (2.25)$$

and $P_\infty(l^2) \langle n \rangle_{l^0 \rightarrow l^2}$ follows from interchanging 1 and 2 on the right-hand side (rhs) of (2.25). One can straightforwardly show that $(\partial/\partial z)\epsilon_{ij}$ at $z=1$ is bounded with respect to N in $d \geq 3D$, but not in $2D$. The average walk length to trap l , given by

$$\frac{\partial}{\partial z} [(1-z)\bar{P}(l^i)]_{z=1} / \bar{P}_\infty(l^i),$$

for $t=2$ becomes

$$\frac{1}{N-2} \frac{\partial}{\partial z} \left[\frac{(1-z)^{-1}(-\epsilon_{12})}{G(0)(-2\epsilon_{12}) - \epsilon_{12}^2} \right]_{z=1} = \langle n \rangle$$

for both l^1 and l^2 (as required, since l^1 and l^2 are equivalent). Corresponding expressions for $t \geq 3$ can be easily obtained, but are rather complicated.

III. LARGE- N ASYMPTOTIC RESULTS FOR SYMMETRIC NEAREST-NEIGHBOR RANDOM WALKS ON A SQUARE LATTICE

As demonstrated in the previous section, the quantities of interest here can be obtained from the behavior of $\Phi(0,z)$ and the ϵ_{ij} , as $z \rightarrow 1$. For symmetric nearest-neighbor random walks on a square lattice, these are determined from the appropriate structure function, $\lambda(\theta_1, \theta_2) = \frac{1}{2}(\cos\theta_1 + \cos\theta_2)$. From Montroll's analysis,³ we have that

$$\begin{aligned} \Phi(0,1) &= \frac{1}{\pi} \ln N + 0.195056 - 0.1170N^{-1} \\ &\quad - 0.051N^{-2} + O(N^{-3}). \end{aligned} \quad (3.1)$$

Our primary task is thus to determine, for $z=1$ (assumed implicitly below), the $\epsilon_{ij} \equiv \epsilon(r,s)$, say, where $r(s)$ denotes the horizontal (vertical) separation in lattice vectors between the sites i and j . Clearly, we have that $\epsilon(r,s) = \epsilon(s,r)$, the $\epsilon(\pm r, \pm s)$ are equal, and we already know that $\epsilon(1,0) = -1$, and that

$$\epsilon(r,s) \sim -(1/\pi)\ln(r^2 + s^2),$$

for large $r^2 + s^2$.

Here we are content to determine the $\epsilon(r,s)$ to leading order in $N = L^2$, as illustrated by the (Euler-McLauren formula based) decomposition

$$\epsilon(r,s) = L^{-2} \sum_{k_1, k_2=0}^{L-1} \frac{\exp[2\pi i(rk_1 + sk_2)] - 1}{1 - \frac{1}{2} \left[\cos \left[\frac{2\pi k_1}{L} \right] + \cos \left[\frac{2\pi k_2}{L} \right] \right]} = \epsilon_0(r,s) + O(N^{-1/2}), \quad (3.2)$$

where

$$\epsilon_0(r,s) = -\frac{2}{\pi^2} \int_0^\pi d\theta_1 \int_0^\pi d\theta_2 \frac{1 - \cos(r\theta_1)\cos(s\theta_2)}{2 - \cos\theta_1 - \cos\theta_2}. \quad (3.3)$$

It is obvious that

$$\epsilon_0(1,0) + \epsilon_0(0,1) = -\frac{2}{\pi^2} \int_0^\pi \int_0^\pi d\theta_1 d\theta_2 = -2,$$

so $\epsilon_0(1,0) = \epsilon_0(0,1) = -1$, as required. All of the $\epsilon_0(r,s)$ can be evaluated exactly as demonstrated below.¹⁷

One can easily show that

$$\begin{aligned} \epsilon_0(r,0) &= -\frac{2}{\pi} \int_0^\pi d\theta_1 \frac{1 - \cos(r\theta_1)}{(1 - \cos\theta_1)^{1/2}(3 - \cos\theta_1)^{1/2}} \\ &= -\frac{2}{\pi} \int_{-1}^{+1} dx \frac{F_{|r|-1}(x)}{(1+x)^{1/2}(3-x)^{1/2}}, \end{aligned} \quad (3.4)$$

where $F_r(x) = [1 - T_{r+1}(x)]/(1-x)$ is an r th-order polynomial (T_r denotes the first kind of Tschebysheff polynomial of order r). A recursive formula relating $\int dx x^n/(a+bx+cx^2)^{1/2}$ for different n allows exact evaluation of (3.4). Note that making the transformation $\phi = r\theta_1$ in the first expression for $\epsilon_0(r,0)$, and expanding

$$\left[1 - \cos \frac{\phi}{r}\right]^{1/2} = 2^{-1/2} \frac{\phi}{r} [1 + O((\phi/r)^2)]$$

shows that $\epsilon_0(r,0) \sim -2 \ln r / \pi$, as $r \rightarrow \infty$ (as required). To evaluate

$$\begin{aligned} \delta\epsilon_0(r,s) &\equiv \epsilon_0(r,s) - \epsilon_0(r,0) \\ &= \frac{2}{\pi^2} \int_0^\pi d\theta_1 \int_0^\pi d\theta_2 \frac{\cos(r\theta_1)[\cos(s\theta_2) - 1]}{2 - \cos\theta_1 - \cos\theta_2} \end{aligned} \quad (3.5)$$

TABLE I. Transcendental forms for $\epsilon_0(r,s)$ for random walks on a 2D square lattice.

$s \backslash r$	1	2	3	4
0	-1	$\frac{8}{\pi} - 4$	$\frac{48}{\pi} - 17$	$\frac{736}{3\pi} - 80$
1	$-\frac{4}{\pi}$	$1 - \frac{8}{\pi}$	$8 - \frac{92}{3\pi}$	$49 - \frac{160}{\pi}$
2	$1 - \frac{8}{\pi}$	$-\frac{16}{3\pi}$	$-1 - \frac{8}{3\pi}$	$12 - \frac{472}{15\pi}$

(which is clearly bounded as $r \rightarrow \infty$, for fixed s), we start by rewriting

$$\begin{aligned} \cos(s\theta_2) - 1 &= H_1(\cos\theta_1, \cos\theta_2)(2 - \cos\theta_1 - \cos\theta_2) \\ &\quad + H_2(\cos\theta_1). \end{aligned}$$

For $|s| \leq |r|$, only the H_2 term contributes to (3.5) which can be rewritten as a single integral of the form

$$\begin{aligned} \delta\epsilon_0(r,s) &= -\frac{1}{\pi} \int_{-1}^{+1} dx \frac{T_{|r|}(x)}{(1+x)^{1/2}(3-x)^{1/2}} G_{|s|}(x) \\ &\quad \text{for } |s| \leq |r|, \end{aligned} \quad (3.6)$$

where $G_1(x) = 1$, $G_2(x) = 6 - 2x$, $G_3(x) = 25 - 20x + 4x^2, \dots$. Clearly, (3.6) can be evaluated exactly.

In Table I, we have presented transcendental forms for several $\epsilon_0(r,s)$ and, in Table II, a more extensive set of numerical values which should be compared with the asymptotic behavior $-(1/\pi)\ln(r^2 + s^2)$. Note the monotonic increase in magnitude of $\epsilon_0(r,s)$ with increasing $r^2 + s^2$, as must be the case given their relationship to site-specific walk lengths for a single trap [here

FIG. 3. Infinite-lattice trapping probabilities for the leftmost trap, l_T^1 , in a pair, and linear triple of traps.

$\langle n \rangle_{l^0} = -\epsilon_{10}N \sim -\epsilon_0(r,s)N$, as $N \rightarrow \infty$, where $l^0 = (r,s)$.

In Fig. 3 we have shown, for various starting sites, the $N \rightarrow \infty$ values of the probability, $P_\infty(l^1)$, that the walker is captured by the end trap l^1 in a pair or in a linear triple of traps. Clearly, as the starting site becomes far removed from the cluster of traps, these site-specific probabilities converge to the lattice average trapping probability $\bar{P}_\infty(l^1)$. This follows from (2.15), (2.16), and the logarithmic behavior of the ϵ_{ij} for large $\|i-j\|$. To illustrate the latter quantities, we consider the cases of linear and bent connected triples of traps l^1, l^2, l^3 , where the central one is l^2 , and use (2.19) to show that as $N \rightarrow \infty$,

$$\begin{aligned} \frac{N-5}{N} S_3 \bar{P}_\infty(l^1) - \frac{1}{N} &= \begin{vmatrix} 1 & \epsilon(1,0) & \epsilon(1,0) & \epsilon(1,0) & \epsilon(1,0) \\ 1 & 0 & \epsilon(1,1) & \epsilon(2,0) & \epsilon(1,1) \\ 1 & \epsilon(1,1) & 0 & \epsilon(1,1) & \epsilon(2,0) \\ 1 & \epsilon(2,0) & \epsilon(1,1) & 0 & \epsilon(1,1) \\ 1 & \epsilon(1,1) & \epsilon(2,0) & \epsilon(1,1) & 0 \end{vmatrix} \\ &= \epsilon(2,0)^2 [\epsilon(2,0)^2 - 4\epsilon(2,0)\epsilon(1,0) + 8\epsilon(1,1)\epsilon(1,0) - 4\epsilon(1,1)^2] \\ &\rightarrow 0 \text{ as } N \rightarrow \infty. \end{aligned} \quad (3.8)$$

Reduction of this determinant to polynomial form (which was simplified by symmetries and Coates graph techniques) is unnecessary if one notes that, as $N \rightarrow \infty$, all rows sum to -3 , guaranteeing a vanishing $N \rightarrow \infty$ limit.

Finally, we consider site-specific walk lengths, $\langle n \rangle_{l^0}$, and corresponding lattice averages, $\langle n \rangle$, for various connected arrays of traps. Let (r,s) denote the position of l^0 . Then for a single trap at the origin $(0,0)$, $\langle n \rangle_{l^0} = -\epsilon_{10}N \sim |\epsilon_0(r,s)|N$, as $N \rightarrow \infty$, so the dominant $N \rightarrow \infty$ behavior can be read off from Tables I and II. For an adjacent pair of traps at $(0,0)$ and $(0,1)$, one has

$$\langle n \rangle_{l^0} \sim \frac{1}{2} [|\epsilon_0(r,s)| + |\epsilon_0(r-1,s)| - 1]N,$$

$$\begin{aligned} \bar{P}_\infty(l^{1,3}) &= \begin{cases} \frac{\pi}{8} \approx 0.3927 \text{ (linear)} \\ \frac{1}{4} \left[1 - \frac{1}{\pi} \right]^{-1} \approx 0.3667 \text{ (bent)}, \end{cases} \\ \bar{P}_\infty(l^2) &= \begin{cases} 1 - \frac{\pi}{4} \approx 0.2146 \text{ (linear)} \\ \left[\frac{1}{2} - \frac{1}{\pi} \right] \left[1 - \frac{1}{\pi} \right]^{-1} \approx 0.2665 \text{ (bent)}. \end{cases} \end{aligned} \quad (3.7)$$

In Table III we have presented trapping probabilities for all members of linear strings of traps of length m (so $t=m$) for $1 \leq m \leq 20$.

It is also interesting to consider trapping probabilities for decimated linear strings of traps. Here the results can be interpreted in the context of *particle-cluster aggregation* as describing what proportion of the linear and various branched clusters are formed by aggregation with a linear cluster. For example, for aggregation with a dimer (adjacent pair), as $N \rightarrow \infty$, 42.73% (57.27%) of the trimers formed are linear (bent). A more extensive set of results for aggregation with m -mers (so $t=3m+2$), for $1 \leq m \leq 16$, is shown in Table IV.

It is obvious, particularly in the context of the above example, that a trap for which all nearest neighbors are also traps cannot be reached by the walker, and thus has zero trapping probability (see the remarks in Sec. II). Obviously this is true for the simpler $N \rightarrow \infty$ form of trapping probabilities, and reflects rather complicated relationships between the $\epsilon_0(r,s)$. The simplest example is a decimated single trap l^1 ($m=1$ above) where one has that

as $N \rightarrow \infty$, for which some values are shown in Fig. 4. For t traps, we have from (2.22) and (3.1) that

$$\begin{aligned} \langle n \rangle &= \frac{N}{N-t} [N\Phi(0,1) - \delta N + O(N^{1/2})] \\ &= \frac{N}{N-t} \left[\frac{1}{\pi} N \ln N + (0.195056 - \delta)N + O(N^{1/2}) \right], \end{aligned} \quad (3.9)$$

and here we shall provide δ values for a range of trap configurations.

For an adjacent pair of traps one has $\delta = \frac{1}{2}$, and for a

connected linear [bent] triple of traps $\delta = \pi/4 \approx 0.785\,398$ [$\delta = (\pi/2)(\pi-1)^{-1} \approx 0.733\,471$]. In Table V, we have displayed δ values for linear strings of m traps with $1 \leq m \leq 20$ (so $t=m$), and in Table VI, δ values obtained from decimating a string of m traps (to produce $2m+2$ extra traps, so $t=3m+2$) are displayed for $1 \leq m \leq 16$. In both cases we have also given values of

$$\Delta_m = (\delta_m - \delta_{m-1}) / [\ln(t+\alpha) - \ln(t-1+\alpha)]$$

for a few choices of α , in order to estimate $\Delta = \lim_{m \rightarrow \infty} \Delta_m$ (which is independent of α). This corresponds to fitting δ_m to the asymptotic behavior $\delta_m \sim \Delta \ln[\beta(t+\alpha)]$. Note that $\mathcal{P} = 2(m+1)$ [$\mathcal{P} = 2(m+3)$] corresponds to the standard choice of perimeter function for the linear string [decimated linear string] of m traps. Our speculation that $\Delta = 2/\pi$ (see the previous section) is supported by the results for the linear string of traps, and not inconsistent with results for the decimated string. In the former case we have chosen an optimal α value, so $\Delta_{20} = 2/\pi$, and checked that the Δ_m varies slowly from $2/\pi$ as m is reduced from 20. For a decimated single trap ($m=1$, $t=5$), the result $\delta=1$, obtained previously in Ref. 9, follows trivially from the observation² that the mean walk length for return to the origin on a perfect finite lattice is N [cf. (4.6)]. For a general decimated linear string of traps, reduction in the average walk length with increasing string length reflects the increase in the rate of destruction by irreversible aggregation with random walkers of corresponding immobile linear clusters (in the same walker or cluster gas environment).

A limited set of results for the 2D triangular lattice, analogous to those discussed in this section, are presented in Appendix B.

IV. EXACT ANALYSIS OF RANDOM WALKS ON FINITE LATTICES WITH MULTIPLE TRAPS

Here we consider only symmetric nearest-neighbor random walks on a finite 2D square lattice (of N sites) with periodic boundary conditions, and one or more completely adsorbing traps. Extension to more-complicated walks is straightforward. For the case of a single trap, there are extensive previous calculations for the site-specific mean walk length (providing the lattice-averaged walk length) until trapping. We start by demonstrating the straightforward extension to the case of multiple traps, $L = \{l_T^1, l_T^2, \dots, l_T^t\}$, where analysis is always based on the intuitively obvious set of equations

$$\langle n \rangle_l = \frac{1}{4} \sum_m (\langle n \rangle_m + 1), \quad l \notin L. \quad (4.1)$$

Here the sum is over sites adjacent to l , and we set $\langle n \rangle_{l_T^i} = 0$. The average walk length is again calculated from $\langle n \rangle = (N-t)^{-1} \sum_{l \notin L} \langle n \rangle_l$.

We use the example of an adjacent pair of traps on a lattice of size $N=L^2$, with L even, for illustration. Reflection symmetry about horizontal and vertical axes through the traps guarantees equivalence of various sites. Nonequivalent ones can be labeled as shown in Fig. 5 for $L=14$. [The reason why we did not choose a more con-

veniently shaped $(L) \times (L-1)$ lattice is because we want to compare with the asymptotic large $N=L^2$ results of the previous section.] The equations (4.1) for this case, rewritten in matrix form, become

$$A \cdot \begin{bmatrix} \langle n \rangle_1 \\ \langle n \rangle_2 \\ \vdots \end{bmatrix} = \begin{bmatrix} 1 \\ 1 \\ \vdots \end{bmatrix}, \quad (4.2)$$

where the "fundamental" matrix A satisfies $A \equiv I + \Delta$ with (cf. Fig. 5)

$$\Delta \equiv \begin{bmatrix} -\frac{1}{4} & 0 & -\frac{1}{4} & -\frac{1}{4} & 0 & 0 & 0 & 0 & 0 & 0 & 0 & \dots \\ 0 & 0 & -\frac{2}{4} & 0 & -\frac{1}{4} & 0 & 0 & 0 & 0 & 0 & 0 & \dots \\ -\frac{1}{4} & -\frac{1}{4} & 0 & 0 & 0 & -\frac{1}{4} & -\frac{1}{4} & 0 & 0 & 0 & 0 & \dots \\ -\frac{1}{4} & 0 & 0 & -\frac{1}{4} & 0 & -\frac{1}{4} & 0 & -\frac{1}{4} & 0 & 0 & 0 & \dots \\ 0 & -\frac{1}{4} & 0 & 0 & 0 & 0 & -\frac{2}{4} & 0 & -\frac{1}{4} & 0 & 0 & \dots \\ 0 & 0 & -\frac{1}{4} & -\frac{1}{4} & 0 & 0 & 0 & 0 & 0 & -\frac{1}{4} & -\frac{1}{4} & \dots \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \dots \end{bmatrix} \quad (4.3)$$

Solution of (4.2) is obtained by matrix inversion. If additional equivalent sets of sites in the above case are decimated (to create a multiple-trap problem preserving the symmetry of the two-trap problem), the corresponding matrices are obtained from A (or Δ) by removing the rows and columns corresponding to the additional traps. For example $A(m) = \{(\underline{A})_{ij}, \text{ for } i, j \geq m\}$ corresponds to decimating sites labeled $1, 2, \dots, m-1$ [so $A(1) \equiv A$]. The similarly defined $\Delta(3)$ and $\Delta(6)$ submatrices are indicated

above in (4.3).

Results from these calculations applied to determination of the average walk length $\langle n \rangle$ for various lattice sizes $N=L^2$ are presented for linear strings of m traps (so $t=m$) with $1 \leq m \leq 9$ in Table VII, for a bent triple of traps in Table VIII, and after decimating a linear string of m traps (where $t=3m+2$) with $1 \leq m \leq 9$ in Table IX. Values of δ obtained from setting $\langle n \rangle$ equal to $(1/\pi)N \ln N + (0.195056 - \delta)N$ are also listed, and their

TABLE V. Random walks on a square lattice of N sites with a linear string of m traps. Values of δ_m in $\langle n \rangle = (N/N-t)[\Phi(0,1) - \delta_m N + O(N^{1/2})]$, and of $\Delta_m = (\delta_m - \delta_{m-1})/[\ln(t+\alpha) - \ln(t+\alpha-1)]$ (cf. $2/\pi = 0.636620$), are shown.

are decimated can be obtained from (4.6) as

$$\begin{aligned} \langle n \rangle'_j &= \langle n \rangle_j - (P_j^1 \langle n \rangle_1 + P_j^2 \langle n \rangle_2) \\ &= \sum_i [(A^{-1})_{ji} - P_j^1 (A^{-1})_{1i} - P_j^2 (A^{-1})_{2i}] \quad \text{for } j \geq 3. \end{aligned} \quad (4.8)$$

An alternative and more complete understanding of this result comes from the observation that (see Appendix C)

$$[A(3)^{-1}]_{ji} = (A^{-1})_{ji} - P_j^1 (A^{-1})_{1i} - P_j^2 (A^{-1})_{2i} \quad \text{for } i, j \geq 3, \quad (4.9)$$

TABLE VIII. Random walks on an $L \times L$ square lattice with a bent triple of traps. $\langle n \rangle$ and δ as in Table VII.

27	1142.60	0.732351

and, thus, that the sum in (4.8) can be taken over $i \geq 3$ only (rather than $i \geq 1$). Equation (4.9) is characteristic of the general relationship between inverses of fundamental matrices for the original and decimated problems. Each row of the decimated inverse is obtained from the corresponding row of the original inverse after subtracting a trapping probability weighted average of rows (in the original inverse) corresponding to sites decimated to traps. This result generalizes the procedure given by Walsh and Kozak for some simple special cases.¹⁹

Finally, we consider the mean walk lengths $\langle n \rangle'_i$ for a walker starting at site i to be adsorbed at trap l_T . Clearly one has that

$$P_l^i \langle n \rangle'_i = \frac{1}{4} \sum_m P_m^i (\langle n \rangle'_m + 1), \quad l \notin L \quad (4.10)$$

which can be solved for the $\langle n \rangle'_i$ given knowledge of the P_l^i from (4.4). Equation (4.10) implies that

$$\left[\sum_{i=1}^t P_l^i \langle n \rangle'_i \right] = \frac{1}{4} \sum_m' \left[\left[\sum_{i=1}^t P_m^i \langle n \rangle'_i \right] + 1 \right]$$

consistent with the requirement that $\langle n \rangle'_i \equiv \sum_{i=1}^t P_l^i \langle n \rangle'_i$ [cf. (4.1)]. We can now also calculate trap- i -specific lattice-averaged walk lengths

$$\langle n \rangle^i \equiv \frac{1}{N-t} \sum_{l \notin L} P_l^i \langle n \rangle'_i / P^i, \quad (4.11)$$

which satisfy $\langle n \rangle = \sum_{i=1}^t P^i \langle n \rangle^i$, as required.

Finally we return to the example of a decimated pair of traps (where the decimated sites adjacent to the pair are denoted by 1 and 2 as in Fig. 5). In Table X, we have given values for $\langle n \rangle^1$ and $\langle n \rangle^2$ for a range of lattice sizes. These can be interpreted as lattice-averaged walk lengths for the formation of bent and linear trimers, respectively.

TABLE X. Random walks on an $L \times L$ square lattice after decimating an adjacent pair of traps (producing six additional traps, four on the sides and two on the ends). Values of the corresponding trap-specific average walk lengths are given for various L .

V. CONCLUSIONS

We have shown that the formulation of Montroll can be developed to provide explicit results for the large-lattice-size (N) asymptotic behavior of trapping probabilities and walk lengths on a lattice with multiple traps. Procedures for exact calculation of these quantities on finite lattices ($N \leq 10^3$) were developed. A simple characterization of the reduction of walk lengths for a decimated problem (as compared with the original) leads to an elucidation of the relationship of the matrix structure for the two problems. All of the finite-square-lattice results presented here are for $L \times L$ (square) rather than rectangular lattices. However, the techniques of analysis described here readily extend to the latter case and results for symmetric nearest-neighbor random walks for some corresponding δ values (as defined by $\langle n \rangle = (N/N - t)[(1/\pi)N \ln N + (0.195\,056 - \delta)N]$) are shown in Fig. 6.

These results for $N \rightarrow \infty$ trapping probabilities are particularly significant in the context of Witten-Sander particle-cluster aggregation,¹³ where it is clear that these determine the shape distribution of clusters formed. This applies in the standard case where the cluster nucleates around a single filled site as well as to generalizations, where (nearby) pairs, triples, etc., of filled sites act as nucleation centers.²⁰

For another application, we consider a process where a gas of random walkers irreversibly aggregate, forming immobile clusters (a *Brownian aggregation* process). Mean-field-type kinetic equations for the cluster size (and

FIG. 6. Values of δ in

$$\langle n \rangle = (N/N - t)[(1/\pi)N \ln N + (0.195\,056 - \delta)N]$$

are shown for random walks on various $L \times L'$ square lattices (of $N = L \times L'$ sites) with (a) a single trap, (b) a linear triple of traps aligned with the side of length L . When $L \rightarrow \infty$ with $L - L'$ constant, δ converges to the $L = L'$ value. The deviation from this limit when, e.g., $L \rightarrow \infty$ with $L' = 2L - 1$, is exactly accounted for by a change in c_2 in (2.11a).

shape) distribution in this process are based on identification of appropriate rates for formation and destruction of clusters by aggregations with individual walkers (at the simplest level, ignoring the effect of a walker irreversibly linking two smaller clusters to form a larger one). Each of the former rates is naturally related to (the reciprocal of) the average walk length for a random walk on a suitable sized (N_t) lattice with an appropriate decimated cluster of traps. This time-dependent size N_t is naturally related to the reciprocal of the density ρ_c of clusters of one or more atoms. To see this, one thinks of dividing the lattice into regions of size $N_t \approx 1/\rho_c$ about each such cluster, and considering the fate (i.e., the average walk length) of an additional "test" walker artificially confined to one such region. To assess the validity of this scheme for determining rates, we have performed direct simulations involving a single walker on a lattice with several immobile clusters [where destruction rates are taken as the capture probabilities divided by the average walk length (for capture anywhere)]. These indicate that a choice of equal-sized (N_t) regions for all clusters overestimates (underestimates) destruction rates for larger (smaller) clusters, so a larger (smaller) region should be associated with larger (smaller) clusters. In fact, it appears that the sizes of these regions should be chosen so as to equalize average

walk lengths, and then (for comparison with the walker-multiple-cluster simulations) destruction rates are taken as the fraction of the total unoccupied area associated with regions surrounding clusters of the size and shape under consideration, divided by this equalized walk length. Corresponding shape-specific creation rates involve an additional appropriate capture probability factor. The resulting kinetic equations do not have the standard Smoluchowski form²¹ because of the complicated functional dependence of average walk lengths on N . Such equations will be investigated in later work.

All these analyses could be extended to include the effect of attractive or repulsive interactions in particle-cluster aggregation²² by introducing more traps surrounding the cluster or introducing trapping probabilities less than unity, respectively. A further natural extension involves calculation of (complete) walk-length distributions (rather than just the means). Its use in the analysis of simple single-cluster growth models has already been suggested.²³ These distributions could also be applied to the development of non-Markovian kinetic equations for Brownian aggregation. Finally, we remark on the need for a more sophisticated analysis of the appropriate $t \times t$ determinant structure for a large number of traps, t , in order to provide a more detailed understanding of the basic quantities of interest in this regime. For example, we would like quantitative estimates of the shielding effect by the arms of fractal clusters (from trapping close to the cluster nucleus).

APPENDIX A: DETERMINANTS VIA COATES GRAPHS

Evaluation of $\det\{g_{ij}\}$, where $1 \leq i, j \leq t$, can be achieved by first constructing a Coates flow graph G , involving points $1, 2, \dots, t$ where each nonzero g_{ij} is represented by a directed bond from i to j , with "transmittance" g_{ij} . If H is a subgraph of G , then $\Pi(H)$ denotes the product of transmittances, and $c(H)$ the number of one-way circuits. Then one has that¹⁴

$$\det\{g_{ij}\} \equiv \det G = (-1)^t \sum_{H \in S} (-1)^{c(H)} \Pi(H),$$

where S is the set of spanning subgraphs in which each (disconnected) component is a one-way circuit. The simplest application of this result here is the determination of $\det\{\epsilon_{ij}\}$ where $\epsilon_{ij} = \epsilon_{ji}$ and $\epsilon_{ii} = 0$. Some examples are given in Fig. 7. Examples for the more complicated determination of

$$\det \left[\begin{array}{c} 1 \\ \circlearrowleft \\ 2 \end{array} \right] = -1 \circlearrowleft 2$$

$$\det \left[\begin{array}{c} 1 \\ \triangle \\ 2 \quad 3 \end{array} \right] = 2 \triangle 2 \quad 3$$

$$\det \left[\begin{array}{c} 1 \\ \square \\ 2 \quad 3 \quad 4 \end{array} \right] = -2 \triangle 1 \quad 3 \quad 4 - 2 \triangle 1 \quad 3 \quad 4 - 2 \triangle 1 \quad 3 \quad 4$$

$$+ \triangle 1 \quad 3 \quad 4 + \triangle 1 \quad 3 \quad 4 + \triangle 1 \quad 3 \quad 4$$

FIG. 7. Diagrammatic representation of $\det\{\epsilon_{ij}\}$ for $t=2,3,4,\dots$. Each line on the rhs represents a factor of ϵ_{ij} . Factors of 2 are associated with circuits of more than two points since the flow can have two directions (flow arrows can be dropped since $\epsilon_{ij}=\epsilon_{ji}$).

$$\begin{vmatrix} 1 & \epsilon_{12} & \epsilon_{13} & \cdots \\ 1 & \epsilon_{22} & \epsilon_{23} & \cdots \\ \vdots & \vdots & \vdots & \ddots \end{vmatrix}$$

are shown in Fig. 8. Here summation over permutations of labels leads to expressions for S_t .

APPENDIX B: RANDOM WALKS ON A TRIANGULAR LATTICE WITH TRAPS

It is convenient to shear the triangular lattice, as described by Montroll,³ so that its sites superimpose those

$$\lambda(\theta_1, \theta_2) = \frac{1}{3} [\cos\theta_1 + \cos\theta_2 + \cos(\theta_1 - \theta_2)],$$

as

$$\epsilon_0(r, s) = \frac{1}{(2\pi)^2} \int_{-\pi}^{+\pi} d\theta_1 \int_{-\pi}^{+\pi} d\theta_2 [\cos(r\theta_1)\cos(s\theta_2) - \sin(r\theta_1)\sin(s\theta_2) - 1] / [1 - \lambda(\theta_1, \theta_2)].$$

It is a straightforward matter to show that²⁴

$$\epsilon_0(r, 0) = -\frac{3}{2\pi} \int_{-\pi}^{\pi} d\theta_1 \frac{1 - \cos(r\theta_1)}{(1 - \cos\theta_1)^{1/2} (7 - \cos\theta_1)^{1/2}}$$

$$= -\frac{3}{\pi} \int_{-1}^{+1} dx \frac{F_{|r|-1}(x)}{(1+x)^{1/2} (7-x)^{1/2}},$$

where $F_r \equiv (1 - T_{r+1})/(1-x)$, as previously. Clearly $\epsilon_0(r, 0) \sim -(2/\pi) \ln r$ from arguments analogous to those given in Sec. III. A more complicated analysis shows that²¹

$$\epsilon_0(r, 1) = \frac{3}{4\pi} \int_{-\pi}^{+\pi} d\theta_1 K_r(\cos\theta_1)$$

$$- \frac{3}{4\pi} \int_{-\pi}^{+\pi} d\theta_1 \frac{2 + K_r(\cos\theta_1)(3 - \cos\theta_1)}{(1 - \cos\theta_1)^{1/2} (7 - \cos\theta_1)^{1/2}},$$

where

$$\det \left[\begin{array}{c} 1 \\ \circlearrowleft \\ 2 \end{array} \right] = -1 \circlearrowleft 2$$

$$\det \left[\begin{array}{c} 1 \\ \triangle \\ 2 \quad 3 \end{array} \right] = \triangle 1 \quad 3 + \triangle 1 \quad 3 - \triangle 1 \quad 3$$

$$\det \left[\begin{array}{c} 1 \\ \square \\ 2 \quad 3 \quad 4 \end{array} \right] = -\triangle 1 \quad 3 \quad 4 - \triangle 1 \quad 3 \quad 4 - \triangle 1 \quad 3 \quad 4$$

$$- \triangle 1 \quad 3 \quad 4 - \triangle 1 \quad 3 \quad 4 - \triangle 1 \quad 3 \quad 4$$

$$+ 2 \triangle 1 \quad 3 \quad 4 + \triangle 1 \quad 3 \quad 4 + \triangle 1 \quad 3 \quad 4 + 2 \triangle 1 \quad 3 \quad 4$$

FIG. 8. Diagrammatic representation of

$$\begin{vmatrix} 1 & \epsilon_{12} & \epsilon_{13} & \cdots \\ 1 & \epsilon_{22} & \epsilon_{23} & \cdots \\ \vdots & \vdots & \vdots & \ddots \end{vmatrix}$$

for $t=2,3,4,\dots$. Each line on the rhs represents a factor of ϵ_{ij} . Dashed lines representing factors of unity transmittance are included for completeness only, and can be ignored.

of a square lattice (see Fig. 9). Again we set $\epsilon_{ij} = \epsilon_0(r, s) + O(N^{-1/2})$, where $r(s)$ denotes the horizontal (vertical) separation, in lattice vectors, between sites i and j . Here we determine only $\epsilon_0(r, s)$, the dominant $N \rightarrow \infty$ behavior of $\epsilon(r, s)$, which is given in terms of the triangular-lattice structure function

$$K_r(\cos\theta) = \frac{\sin(r\theta)\sin\theta}{1 + \cos\theta} - \cos(r\theta)$$

$$= (\text{sgn}r)(1-x)U_{|r|-1}(x) - T_{|r|}(x),$$

with $x = \cos\theta$; $\text{sgn}r = -1, 0, 1$ for $r < 0, = 0, > 0$, respectively; and U_r denoting the r th-order Tschchebysheff polynomial of the second kind. The second integral can be reexpressed as

FIG. 9. Shearing of a triangular lattice so that its sites are superimposed on those of a square lattice.

$$-\frac{3}{2\pi} \int_{-1}^{+1} dx \frac{(\operatorname{sgn} r)(3-x)U_{|r|-1}(x) - \tilde{F}_{|r|}(x)}{(1+x)^{1/2}(7-x)^{1/2}},$$

where $\tilde{F}_r(x) \equiv [(3-x)T_r(x) - 2]/(1-x)$ is an r th-order polynomial.

Clearly these integrals for $\epsilon_0(r,0)$ and $\epsilon_0(r,1)$ can be evaluated exactly, and one obtains, e.g.,

$$\epsilon_0(1,0) = -1, \quad \epsilon_0(2,0) = -8 + 6\sqrt{12}/\pi,$$

$$\epsilon_0(3,0) = -81 + 72\sqrt{12}/\pi, \quad \dots$$

$$\epsilon_0(0,1) = -1, \quad \epsilon_0(1,1) = 2 - 3\sqrt{12}/\pi,$$

$$\epsilon_0(2,1) = 15 - \sqrt{12}/\pi, \quad \dots$$

From Fig. 9, it is also obvious that there are various equivalences between the $\epsilon_0(r,s)$. For example, one must have that $\epsilon_0(1,0) = \epsilon_0(0,1) = \epsilon_0(-1,0) = \epsilon_0(0,-1) = \epsilon_0(1,-1) = \epsilon_0(-1,1)$, and $\epsilon_0(-j,k) = \epsilon_0(j-k,k)$. Such equalities are not transparent in the above expressions, however it is obvious, using the basic defining expression for $\epsilon_0(r,s)$, that the six ϵ_0 's for nearest-neighbor sites (listed above) sum to -6 . These results are used in the following calculations.

For a linear, bent, or triangular triple of connected traps l^1, l^2, l^3 (where l^2 is central), we obtain from (2.20) that, as $N \rightarrow \infty$, $\bar{P}_\infty(l^{1,3}) : \bar{P}_\infty(l^2) = 1 : (-6 + 6\sqrt{12}/\pi)$, $1 : (72\sqrt{12}/\pi - 79)$, and $1 : 1$, respectively [so $\bar{P}_\infty(l^{1,3}) \approx 0.3823$, 0.3715 , and 0.3333 , and $\bar{P}_\infty(l^2) \approx 0.2355$, 0.2571 , and 0.3333 , respectively]. For a trap l^1 surrounded by six other traps, the determinant associated with $\bar{P}_\infty(l^1)$, as $N \rightarrow \infty$, can be shown to vanish since all

of its rows sum to -7 [cf. (3.8)]. The change from single-trap behavior in the average walk length $\langle n \rangle$ is reflected by $\delta = -\det\{\epsilon_{ij}\}/S_i$ [cf. (2.22)]. As $N \rightarrow \infty$, we have that $\delta = \frac{1}{2}$ for an adjacent pair of traps, and $\delta = \pi(3\sqrt{12} - 2\pi)^{-1}$, $(2\pi/3)(2\pi - \sqrt{12})^{-1}$, and $\frac{2}{3}$ for a linear, bent, or triangular connected triple of traps, respectively.

APPENDIX C: INVERSES OF DECIMATED FUNDAMENTAL MATRICES

Let \underline{A} denote the fundamental matrix for some multiple-trap problem, and $\tilde{\underline{A}}$ the fundamental matrix for some corresponding decimated problem. We shall thus write

$$\underline{A} = \begin{bmatrix} \underline{B} & \underline{C} \\ \underline{D} & \tilde{\underline{A}} \end{bmatrix} \quad \text{and} \quad \underline{A}^{-1} = \begin{bmatrix} \underline{X} & \underline{Y} \\ \underline{Z} & \underline{U} \end{bmatrix}.$$

Then from the standard relations $\underline{U} = (\tilde{\underline{A}} - \underline{D}\underline{B}^{-1}\underline{C})^{-1}$ and $\underline{Y} = -\underline{B}^{-1}\underline{C}\underline{U}$, one has that $\tilde{\underline{A}}^{-1} = \underline{U} + \tilde{\underline{A}}^{-1}\underline{D}\underline{Y}$ or

$$(\tilde{\underline{A}}^{-1})_{ji} = (\underline{U})_{ji} + \sum_k \left[\sum_m (\tilde{\underline{A}}^{-1})_{jm} (\underline{D})_{mk} \right] (\underline{Y})_{ki}.$$

Finally, from (4.4) [or (4.5)], one can straightforwardly make the identification

$$P_j^k \equiv \sum_m (\tilde{\underline{A}}^{-1})_{jm} (\underline{D})_{mk}$$

for the probability of capture at trap l_j^k for a walker starting at site j .

⁶(a) K. E. Shuler, H. Silver, and K. Lindenberg, J. Stat. Phys. 15, 393 (1976). (b) For this result to be valid, one would require that infinite-square-lattice behavior, $S_n \sim \pi n / \ln n$ as $n \rightarrow \infty$, also apply to an $L \times L$ (N -site) square lattice (with periodic boundary conditions) for $n = O(N \ln N)$. Clearly, the finite and infinite lattice S_n are equal for $0 \leq n \leq L-1$, and thereafter the former is smaller, approaching N as $n \rightarrow \infty$. For either a finite or infinite perfect lattice, one has that $S(z) = \sum_{n=0}^{\infty} z^n S_n = (1-z)^{-2} [G(0,z)]^{-1}$, where $G(0,z)$ is the corresponding generating function (Ref. 2). For an N -site square lattice $G(0,z) = N^{-1}(1-z)^{-1} + \Phi(0,z)$ [see (2.10)], and one can easily show that (Ref. 2) $\Phi(0,z) \sim -\pi^{-1} \ln(1-z)$ for $1 \gg 1-z \gg N^{-1}$, and that (Ref. 3) $\Phi(0,z) \sim -\pi^{-1} \ln N + c_1 + c_2 N^{-1} + \dots + O(1-z)^{1/2}$ for $1 \gg N^{-1} \gg 1-z$. This suggests that the first (infinite-lattice) form of $\Phi(0,z)$ is also valid for $1-z = O(N^{-1})$, and thus that the infinite-lattice form of S_n is valid for $n \leq O(N)$.

¹³T. A. Witten and L. M. Sander, Phys. Rev. Lett. 47, 1400 (1982); Phys. Rev. B 27, 5686 (1983). Here each walker is introduced randomly at a large distance from the aggregating cluster and either walks in and sticks to the cluster or wanders out too far and is destroyed (before the next walker is introduced). In the large-distance limit, trapping probabilities are clearly the same as the $N \rightarrow \infty$ lattice-averaged trapping probabilities obtained from our calculations (where almost all walkers have come in from an infinite distance).

¹⁴See, for example, S. Kirkpatrick, Rev. Mod. Phys. 45, 574 (1974); S. Kivelson, Phys. Rev. B 21, 5755 (1980); H. Scher and C. H. Wu, Proc. Natl. Acad. Sci. 78, 22 (1981).

¹⁶Note that if $\alpha_{ij} = 1 + \delta_{ij}a_i$, then $\det\{\alpha_{ij}\} = \prod_k a_k [1 + \sum_k (1/a_k)]$.

¹⁷A more detailed asymptotic analysis could follow that of Montroll (Ref. 3). One can straightforwardly show that the

contribution to $\epsilon(r,s)$ from $k_1=0$ in (3.2) is given by $\frac{1}{3}(1-6s/L+6s^2/L^2-1/L^2)+O(1-z)^{1/2}$.

¹⁸We note that $(1/\pi)\int_0^\pi d\theta(a+b\cos\theta)^{-1}=(a^2-b^2)^{-1/2}$ for $a^2>b^2$ and $a>b$.

¹⁹The procedure outlined in Ref. 9 where a simple average is taken over all trap rows only applies in special cases where all trapping probabilities are equal.
